Abstract

Background: Dipeptidyl peptidase-4 (DPP-4) inhibitors and sodium–glucose co-transporter 2 (SGLT2) inhibitors improve hyperglycemia, and the usefulness of co-administration of DPP-4 inhibitors and insulin therapy has been well established. However, it has been still uncertain whether combination therapy of SGLT2 inhibitors and insulin is superior to that of DPP-4 inhibitors and the latter. Therefore, we investigated the superiority of dapagliflozin on glucose fluctuation compared with DPP-4 inhibitors in patients with type 2 diabetes mellitus (T2DM) on insulin using a continuous glucose monitoring (CGM) system.

Methods: In this prospective, randomized, open-label controlled trial, 36 patients with T2DM and treated with DPP-4 inhibitors and insulin therapy, were enrolled and allocated into two groups. The patients either switched their DPP-4 inhibitors to dapagliflozin 5 mg for 12 weeks, or continued their DPP-4 inhibitors for the same period. CGM analyses and metabolic markers were assessed before and after treatment periods.

Results: In total, data from 29 patients were analyzed. There were no significant differences in the mean amplitude of glycemic excursions and other CGM profiles in either group after treatment. Within the dapagliflozin treatment group, significant reductions of body mass index and albuminuria, and increases of HbA1c, hemoglobin and hematocrit were observed, but improvement of albuminuria was not significant if compared with the DPP-4 continuation group.

Conclusions: Combination therapy of dapagliflozin and insulin was not superior in glucose fluctuation to DPP-4 inhibitors on insulin. However, dapagliflozin may in part provide favorable effects on metabolism in patients with T2DM treated with insulin therapy.

Background

Important goals for treatment of patients with diabetes mellitus include suppression of macro- and microvascular complications and maintenance of good mortality related with these patients' high risk for cardiovascular diseases (CVD) [1]. Recent comprehensive care to avoid cardiovascular risk factors dramatically reduced diabetic complications [2]; however, the mortality is still higher in patients with diabetes compared with that of those without [3]. Recently it has been suggested that glucose fluctuation is closely related to endothelial cell damage [4], known to be the first stage of atherosclerosis and a predictor of CVD [5]. Moreover, mean amplitude of glycemic excursions (MAGE), which is a marker of daily blood glucose variability relating to higher postprandial blood glucose or hypoglycemia, is known to be an important factor in determining the severity of coronary artery disease, independent of HbA1c. It is also an independent predictor of mortality [6]. Additionally, MAGE was also reported to correlate closely with oxidative stress in vivo [7]. To overcome the risk of CVD, it would be important to manage glycemic fluctuation.

To date, several anti-hyperglycemic agents are available, but remedies that can suppress glucose variability are limited. One of such agents, dipeptidyl peptidase-4 (DPP-4) inhibitors, has been known to exert glucose level dependent hypoglycemic action [8]. Additionally, combination therapy using insulin injection and DPP-4 inhibitors has reduced HbA1c levels and hypoglycemic events and also reduced glucose fluctuation such as the M value compared with insulin treatment alone [9, 10]. However, some sodium–glucose co-transporter 2 (SGLT2) inhibitors have been shown to be potent suppressors of cardiovascular risks [11, 12], but the effectiveness of SGLT2 inhibitors on suppressing glucose fluctuations in patients with type 2 diabetes mellitus, especially compared with DPP-4 inhibitors, has not been clarified. In this trial, we aimed to assess the effects of dapagliflozin, one of the SGLT2 inhibitors, on glucose fluctuation in patients with type 2 diabetes mellitus on insulin using a prospective, randomized parallel-group comparison study design.

Methods

Study population

We defined the inclusion criteria as follows: subjects with type 2 diabetes mellitus who were treated with a combination of the usual dose of DPP-4 inhibitors with any kind of insulin therapy for more than 3 months, and aged 20–80 years with an HbA1c level between 6.0 and 9.0%. Other oral hypoglycemics such as metformin, sulphonylureas, glinides, thiazolidine and alpha-glucosidase inhibitors were allowed and continued during the study period. We excluded patients if they were pregnant, had

persistent elevation of serum transaminase levels (more than three times the upper limit of normal), had renal dysfunction [estimated GFR <45 mL min⁻¹ (1.73 m²)⁻¹], or had low body mass index (BMI <22 kg m⁻²).

Protocol

This open-labelled, prospective, randomized, parallel-group comparison study was conducted in Hokkaido University Hospital. Following enrolment, all individuals were randomly assigned to a group by an independent organization at the beginning of the study to either continue their DPP-4 inhibitor treatment or change to dapagliflozin 5 mg once daily according to their age, BMI, HbA1c and eGFR levels. The participants monitored their daily glucose levels during conventional treatment for 3–5 days using a continuous glucose monitoring (CGM) system (iPro2[®], Medtronic MiniMed, Northridge, CA, USA). After initial assessments, they were treated with prior DPP-4 inhibitors or 5 mg dapagliflozin for 12 weeks. The doses of insulin were titrated according to the Japan Diabetes Society guidelines, targeted at <130 mg dL⁻¹ for average pre-meal blood glucose levels and <180 mg dL⁻¹ for average 2-h postprandial glucose levels. Other medications were continued without change and all patients were encouraged to continue diet and exercise therapy during the study period. At the end of the study, glucose monitoring using CGM for 3–5 days was again performed. For biochemical analyses, fasting blood and urine samples were measured at the times of fitting the CGM system.

The primary endpoint of the study was the extent of change in MAGE [13]. Briefly, MAGE was calculated for each subject by taking the arithmetic mean of CGM values increased or decreased (from nadirs to peaks or vice versa) when both ascending and descending segments exceeded the value of one standard deviation (SD) of the CGM values for the same 24-h period. Secondary endpoints were changes in mean blood glucose, SD and hyper- or hypoglycaemia in the CGM (>180 or <70 mg dL⁻¹), surrogate markers of beta-cell function and metabolic parameters. Concerning the diagnosis of diabetic nephropathy, the definition was based on the urine albumin to creatinine ratio ≥ 300 mg g⁻¹ creatinine [14]. The subject enrolment period was from 7 September 2014 to 30 September 2016. The last subject completed the study in February 2017.

Statistical analyses

The sample size was determined by assuming that dapagliflozin would improve MAGE by at least 60 mg dL⁻¹ (SD = 50.0), based on a previous study which assessed efficacy of 5 mg day⁻¹ dapagliflozin in patients with diabetes [15]. It was determined that 32 patients were

needed to detect a significant difference with at least a power of 80% and statistical significance of 5%. To account for the potential loss of subjects, the sample size was set at 36 patients (18 per group). Results are expressed as mean \pm SD or medians and 25–75% quartile. Differences of baseline characteristics between groups were assessed by unpaired *t* test or Mann–Whitney U test for continuous variables and Fisher's exact test for categorical variables. The Kolmogorov–Smirnov test for normality was used to determine the appropriate statistical test for the continuous variables. Analysis was done on the full-analysis set, which was defined as all treated participants with available pre- and post-CGM assessments. For the primary analysis, the effects of dapagliflozin compared with DPP-4 inhibitors on MAGE were assessed by unpaired *t* test. Mean changes of metabolic parameters in both groups between baseline and the end of the survey were analyzed as the secondary analyses. We also employed paired *t* test or Wilcoxon signed-rank test for comparison of pre- and post-treatment. Group comparison for the differences of mean changes was performed using unpaired *t* test or Mann–Whitney U test. A *p* value <0.05 was considered statistically significant. Data were analyzed using Ekuseru-Toukei 2012 software (Social Survey Research Information, Tokyo, Japan).

Results

Baseline characteristics

We enrolled 36 individuals and randomly assigned all participants to two groups with 18 participants each. After enrolment, five participants did not complete the first CGM examination for the following reasons, three for consent withdrawal and one each for relocation and ineligibility to the criteria (low adherence). The remaining 31 participants received the first CGM assessment but two later dropped out. In total, 29 participants completed the CGM assessments.

Because our study was based on treatment assignment, we used the full-analysis set for our analyses. Table 1 presents the baseline characteristics of participants, comprising 12 women and 17 men with a mean age of 61.4 ± 8.7 years and mean HbA1c level of $7.3 \pm 0.8\%$. There were no statistical differences in age, MAGE, levels of HbA1c, duration of diabetes, BMI, liver and renal functions between groups at the baseline. Only sex and urine albumin to creatinine ratio differed. However, prevalence of diabetic nephropathy did not show a significant difference. All were treated with insulin therapy with the usual dose of DPP-4 inhibitors with or without other peroral hypoglycemic agents. None of the participants discontinued dapagliflozin due to adverse events, although

one case discontinued for other reasons as described previously.

Glucose fluctuation and glycemc control

As shown in Table 2 and Figs. 1, 2, the baseline CGM data were not significantly different between groups. During observation periods, MAGE was slightly increased in both groups; however, changes were not statistically significant (dapagliflozin; $p = 0.52$, DPP-4 inhibitors; $p = 0.11$). Similarly, there were no significant changes for mean blood glucose, SD of glucose levels, frequency of high or low blood glucose (>180 or <70 mg dL⁻¹), and night-time hypoglycaemia between pre- and post-treatment in both groups. Concerning the surrogate markers of glycemc control, HbA1c was significantly increased only in the dapagliflozin group ($p = 0.005$), but this change did not show significant differences between the groups ($p = 0.30$) (Table 3). Throughout the study, participants maintained insulin regimens and total insulin dosages did not significantly change.

Other metabolic parameters and relationships between MAGE

Dapagliflozin treatment significantly ameliorated BMI and albuminuria ($p = 0.002$ and 0.045 , respectively) and elevated hemoglobin and hematocrit levels ($p = 0.03$ and 0.01 , respectively), but not between group comparisons of albuminuria and hemoglobin ($p = 0.052$ and 0.13 , respectively). Because there was a significant difference

in the baseline urine albumin-to-creatinine ratio (UACR) between groups, we compared Δ UACR between groups using an analysis of covariance adjusted for the baseline UACR. This analysis also showed that there was no significant difference between Δ UACR in group comparison ($p = 0.21$, adjusted for baseline UACR). In addition, there was no significant correlation between baseline UACR and Δ UACR in the dapagliflozin group ($r = -0.382$, $p = 0.18$). Moreover, in comparison to the DPP-4 continuation group, liver alanine-aminotransferase elevation was significantly improved in the dapagliflozin group ($p = 0.03$) (Table 3).

With dapagliflozin treatment, eGFR was significantly higher in patients with improved MAGE compared

with those without ($p = 0.02$) (Table 4), and the effects of dapagliflozin were partially diminished (not statistically significant) in participants with relatively impaired renal function (Table 5). No other metabolic or baseline characteristics including age, BMI, surrogate markers of glycemic control, duration of diabetes, and insulin doses correlated with improvement in MAGE.

Discussion

In this trial, we aimed to verify the superiority of dapagliflozin to therapy with DPP-4 inhibitors and insulin in type 2 diabetes patients for MAGE. To date, some clinical studies have been conducted on the relationship between glycemic fluctuation and macrovascular risks. The risk factors for cardiovascular events such as endothelial cell function, oxidative stresses, and intra-media thickness were shown to be strongly correlated with glycemic variability in patients with diabetes mellitus [7, 16, 17]. There is no robust evidence that suppression of glycemic variability directly reverses cardiovascular events, but recently, some anti-diabetic remedies that can inhibit glucose fluctuation were shown to improve surrogate markers of cardiovascular risk factors [18, 19]. Therefore, it is important to moderate not only HbA1c but also glycemic fluctuation.

Previous studies have shown that both DPP-4 inhibitors and SGLT2 inhibitors affect glucose fluctuation. DPP-4 inhibitors have a potent hypoglycemic effect during the hyperglycemic state via glucose-dependent insulin secretion by increasing the active serum GLP-1 and GIP concentration, or by reducing hypoglycemia by

diminishing insulin secretion and cancelling glucagon suppression under normal to hypoglycemic conditions [20]. GIP has been reported to act as a potent insulin releaser under hyperglycemic conditions. Other hand, GIP is also thought to be a physiological bifunctional blood glucose stabilizer because insulin secretion action does not occur and the glucagon response was improved under normal or hypo-glycemic conditions [21]. These glucose level-dependent mechanisms of incretins suggest that DPP-4 inhibitors can improve glycemic control and reduce glucose fluctuations in patients with type 2 diabetes mellitus compared with other insulin secretagogues [22]. Concerning the combination of the DPP-4 inhibitors with insulin therapy, meta-analysis revealed that co-administration of DPP-4 inhibitors and insulin injection achieved better glycemic control without increasing hypoglycaemia [23].

SGLT2 inhibitors also possess hypoglycemic actions and a preferable effect on glucose variability. The effects of SGLT2 inhibitors rely on the filtered load of glucose, and thus it is expected that their hypoglycemic action will work potently under hyperglycemic conditions [24]. To avoid hypoglycemia under insufficient SGLT2 conditions, compensatory SGLT1 reabsorption prevents excessive

glycosuria [25] and excessive hypoglycemic action may be inhibited. In addition, increasing the plasma glucagon concentration [26] and hepatic gluconeogenesis [26], and enhancing lipolysis in patients with type 2 diabetes mellitus may also prevent hypoglycemia [27]. A randomized controlled trial using CGM comparing luseogliflozin and a placebo with type 2 diabetes mellitus found significant improvements in glucose variability and mean blood glucose with luseogliflozin [28]. Even in type 1 diabetes mellitus, dapagliflozin also reduced MAGE in a dose dependent manner [15], which provided evidence of the beta-cell independent effect of SGLT2 inhibitors on glucose fluctuation. A recent prospective study comparing the efficacy of administration of SGLT2 inhibitor with a co-administration of DPP-4 inhibitor and SGLT2 inhibitor on multiple insulin injection therapy revealed that there were no significant changes in MAGE and SD on sensor glucose measurements among insulin therapy alone, or with the addition of DPP-4 inhibitors and/or SGLT2 inhibitor. However, night-time hypoglycaemia was significantly decreased in regimen including the SGLT2 inhibitor compared with insulin monotherapy [29].

Our study showed as follows; accompanied with insulin, switching from DPP-4 inhibitors to dapagliflozin

Table 5 Comparison of the effects of dapagliflozin on metabolic parameters with or without renal dysfunction

maintained an equivalent glucose fluctuation and all-day and nocturnal hypoglycaemia prevalence without significant insulin dosage change. However, we could not verify the superiority of dapagliflozin compared with DPP-4 inhibitors in MAGE, and HbA1c deteriorated only in the dapagliflozin group. As described above, the DPP-4 inhibitors' potency in reducing glucose fluctuations has been shown. Switching to dapagliflozin did not show additional improvement on MAGE, which might be because baseline glucose variations were already suppressed in response to the DPP-4 inhibitors in insulin therapy. In addition, this result might be somewhat different if insulin titration was performed to maintain preferable glucose levels in the dapagliflozin group because generally glucose variation is influenced largely by mean blood glucose levels. That is, the higher the mean glucose levels are, the higher the glucose fluctuation will be. Even in DPP-4 continuation, glycemic control worsened in some participants. Our protocol did not allow participants to change the dosage or frequency of their DPP-4 inhibitors or other drugs taken for comorbidities in this group. Thus, deterioration of such changes observed in the DPP-4 inhibitor groups might be a result of adherence to dietary and exercise therapy. Taken together, combination therapy with SGLT2 inhibitors and insulin injection may be superior to insulin monotherapy in avoiding hypoglycaemia, and there seems to be no obvious differences between DPP-4 inhibitors and SGLT2 inhibitors as a partner of insulin in this context.

In addition, our study revealed that patients with improved MAGE after dapagliflozin administration possessed relatively preferable renal function. DPP-4 inhibitors are known to exert hypoglycemic action even with renal dysfunction [30]. On the other hand, the hypoglycemic effects of SGLT2 inhibitors rely on proper renal function. In addition, a previous report which assessed the efficacy of luseogliflozin on individuals with different renal function using CGM revealed that patients with renal insufficiency showed not only attenuated glucose lowering effects but also a lack of SD improvement in the blood glucose [31]. Taken together, the effect on glucose fluctuation of SGLT2 inhibitors may require relatively good renal function.

Both DPP-4 inhibitors and SGLT2 inhibitors have been reported to have some pleiotropic effects on metabolisms other than the hypoglycemic action. Previous reports verified that incretin agents including DPP-4 inhibitors exert renal protective effects *in vitro* and *in vivo* against increased renal oxidative stress under hyperglycemia [32]. The pooled analysis of prospective clinical trials using linagliptin resulted in significant improvement in albuminuria in patients with type 2 diabetes mellitus and renal dysfunction independent of

changes in blood glucose and blood pressure [33]. Our study showed that albuminuria improved only in the dapagliflozin group after switching from DPP-4 inhibitors, but not between group comparison in the absence of a change in glucose fluctuation and blood pressure. The impact of SGLT2 inhibitors on renal protection has recently attracted much attention. In the diabetic state, the tubuloglomerular feedback system is known to break down and to result in causing glomerular hyper-filtration. It has been revealed that SGLT2 inhibitors reduced the reabsorption of glucose in the proximal tubule resulting in normalized tubuloglomerular feedback and glomerular hyper-filtration [34]. Although there are only a few large-scale clinical trials that have focused on the impact of SGLT2 inhibitors on renal protection, one of the SGLT2 inhibitors, empagliflozin, was reported to be associated with slower progression of kidney disease and lower rates of clinically relevant renal events in patients with type 2 diabetes mellitus [35].

Our data also showed significant elevation of hemoglobin and hematocrit with dapagliflozin treatment. These phenomena were thought to be due to up-regulation of erythropoietin rather than dehydration as previously reported [36], and such hematopoietic action might in part exert favorable effects on diabetic kidneys [37].

Finally, dapagliflozin significantly reduced BMI and liver enzyme as expected. Previously, we investigated the effects of ipragliflozin on body composition in Japanese patients with type 2 diabetes mellitus and revealed that body weight loss accompanied with improvement of liver dysfunction was driven mainly by reducing visceral fat mass and reducing water volume [38]. Even with co-administration of SGLT2 inhibitors and insulin injection, a recent meta-analysis reported that this combination resulted in significantly lower HbA1c, body weight and insulin dosage compared with placebo [39]. Considering that DPP-4 inhibitors do not affect body weight and insulin therapy tends to increase it, switching from DPP-4 inhibitors to dapagliflozin might possess merits from this point of view.

The strengths of our study are as follows: this was the first randomized controlled trial directly comparing DPP-4 inhibitors and an SGLT2 inhibitor on glucose fluctuation in insulin therapy; there were no significant biases in the pre-treatment for type 2 diabetes mellitus in both study arms; and we could assess the relationship between glucose fluctuations and other metabolic parameters. However, our small sample size may limit our ability to draw a conclusion. Other major limitations of this study were a lack of double blinding, the short study duration, and a lack of dietary uniformity because of the ambulatory care setting. In addition, some participants withdrew their consent after study inclusion and randomization. To resolve these potential issues, our findings

need to be validated with a larger scaled, long term, dietary-controlled double-blind trial.

Conclusions

In conclusion, combination therapy with dapagliflozin and insulin injection did not show glucose fluctuation superiority over DPP-4 inhibitors on insulin therapy. Although potential pleomorphic effects of dapagliflozin on metabolism might exist, further investigation would be necessary in future.

Abbreviations

CVD: cardiovascular diseases; DPP-4: dipeptidyl peptidase-4; SGLT2: sodium-glucose co-transporter 2; BMI: body mass index; CGM: continuous glucose monitoring; MAGE: mean amplitude of glycemic excursions; SD: standard deviation.

Authors' contributions

HN contributed in writing the manuscript. HN and KO contributed to the data analysis. HN, HM, SY, MO, HS, and AN contributed to patient enrolment. HM, AN, and TA contributed to the discussion, and reviewed and edited the manuscript. HM designed and performed the research and wrote the manuscript. HM is the guarantor of this work and, as such, had full access to all data in the study and takes responsibility for the integrity of the data and accuracy of the data analysis. All authors read and approved the final manuscript.

Author details

¹ Department of Rheumatology, Endocrinology and Nephrology, Faculty of Medicine and Graduate School of Medicine, Hokkaido University, North 15, West 7, Kita-ku, Sapporo, Hokkaido 060-8638, Japan. ² Clinical Research and Medical Innovation Center, Hokkaido University Hospital, North 14, West 5, Kita-ku, Sapporo, Hokkaido 060-8648, Japan.

Acknowledgements

Not applicable.

Competing interests

HM has received honoraria for lectures from Astellas Pharma Inc., AstraZeneca, Daiinippon Pharma Co., Eli Lilly, Kissei, Mitsubishi Tanabe Pharma Co., MSD, Novo Nordisk Pharma, and Sanofi, and has received research funding from Astellas Pharma Inc., AstraZeneca, Eli Lilly, Mitsubishi Tanabe Pharma Co.

AN has received honoraria for lectures from Sanofi.

TA has received honoraria for lectures from Mitsubishi Tanabe Pharma Co., Chugai Pharmaceutical Co., Ltd, Astellas Pharma Inc., Takeda Pharmaceutical Co., Ltd, Pfizer Inc., and AbbVie Inc., and has received research funding from Astellas Pharma Inc., Takeda Pharmaceutical Co., Ltd, Mitsubishi Tanabe Pharma Co., Chugai Pharmaceutical Co., Ltd, Daiichi Sankyo Co., Ltd, and Otsuka Pharmaceutical Co., Ltd.

HN, HS, KO, SY, and MO have no competing interests to declare.

Availability of data and materials

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Ethics approval and consent to participate

The institutional review board of Hokkaido University reviewed and approved the study protocol and written consent was obtained from all participants. The study was registered in the UMIN Clinical Trials Registry System under the identifier UMIN000015033.

Funding

This trial did not supported by anywhere.
